biopolymers

biopolymers are made up of **monomers** and **polymers**. monomers are smaller micromolecules such as nucleic acids, amino acids, fatty acid, and sugar. assembled together as repeating subunits, monomers form long macromolecules which are referred to as polymers.

typical examples of biopolymers

- genes: RNA and DNA
- gene products: peptides and proteins
- biopolymers not coded by genes: lipids, polysaccharides, and carbohydrates

biopolymers are **extremely flexible**. upon **thermal fluctuations**, they may bend from side to side and jiggle around. this is the nature of **soft matter** related to the notion of **entropy**.

4

the cytoskeleton

Figure 1.3. Eukaryotic cytoskeleton. The cytoskeleton provides structural stability and is responsible for force transmission during cell locomotion. Microtubules are thick hollow cylinders reaching out from the nucleus to the membrane, intermediate filaments can be found anywhere in the cytosol, and actin filaments are usually concentrated close to the cell membrane.

3.1 biopolymers - motivation

5

actin filaments

Figure 1.4.1 Actin filaments form tight parallel bundles which are stabilized by cross-linking proteins. Deeper in the cytosol the actin network adopts a gel-like structure, stabilized by a variety of actin binding proteins.

7

the cytoskeleton

actin filaments are 7nm in diameter and consist of two intertwined actin chains. they are tension bearing members of the cell. being located close to the cell membrane, they are responsible for inter- and intracellular transduction. together with myosin, they form the contraction apparatus to generate muscular contraction of skeletal and cardiac muscle.

intermediate filaments are 8-12nm in diameter and thus more stable than actin filaments. they are also tension bearing within a cell. anchoring at organelles, they organize and maintain the three dimensional structure of the cell.

microtubules are hollow cylinders, 25nm in diameter with a 15nm lumen. they are comprised of 13 protofilaments consisting of α and β tubulin. microtubules are organized by the centrosome, but reassemble dynamically. unlike actin and intermediate filaments, microtubules can also bear compression. in addition, they form a highway for intracellular transport.

9

axial deformation - tension

$EA u_{,xx} + f = 0$ with EA ... axial stiffness
cross section area $A = \pi r^2$

	r	A	E	EA
microtubule	12.5 nm	491 nm ²	1.9·10 ⁹ N/m ²	93·10 ⁻⁸ N
intermediate filament	5.0 nm	79 nm ²	2.0·10 ⁹ N/m ²	15·10 ⁻⁸ N
actin filament	3.5 nm	39 nm ²	1.9·10 ⁹ N/m ²	7·10 ⁻⁸ N

Table 3.1: Axial stiffness EA of major constituents of cytoskeleton: microtubules, intermediate filaments and actin filaments

3.2 biopolymers - energy

10

axial deformation - tension

Example Determine the elongation of an active muscle with Young's modulus $E = 40 \text{ MPa} = 4 \cdot 10^7 \text{ N/m}^2$, a cross section of $A = 1000 \text{ mm}^2 = 10^{-3} \text{ m}^2$ and a total length $l = 10 \text{ mm} = 0.01 \text{ m}$! Assume that the muscle is loaded by a weight of $m = 10 \text{ kg}$. What is its elongation Δl and its strain ϵ ? ◦ The force acting on the muscle is $N = mg$ with the acceleration due to gravity $g = 10 \text{ m/s}^2 = 10 \text{ N/kg}$, thus $N = 10 \text{ kg} \cdot 10 \text{ N/kg} = 100 \text{ N}$. The elongation Δl then follows as $\Delta l = \epsilon l = \sigma l / E = N l / [EA] = 100 \text{ N} \cdot 0.01 \text{ m} / [4 \cdot 10^7 \text{ N/m}^2 \cdot 10^{-3} \text{ m}^2] = 2.5 \cdot 10^{-2} \text{ mm}$. The strain simply follows as $\epsilon = \Delta l / l = 2.5 \cdot 10 \text{ mm} / 10 \text{ mm} = 0.0025 = 0.25\%$.

ABSTRACT

Microtubules are rigid cytoskeletal filaments, and their mechanics affect cell morphology and cellular processes. For instance, microtubules for the support structures for extended morphologies, such as axons and cilia. Further, microtubules act as tension rods to pull apart chromosomes during cellular division. Unlike other cytoskeletal filaments (e.g., actin) that work as large networks, microtubules work individually or in small groups, so their individual mechanical properties are quite important to their cellular function. In this review, we explore the past work on the mechanics of individual microtubules, which have been studied for over a quarter of a century. We also present some prospective on future endeavors to determine the molecular mechanisms that control microtubule rigidity.

Published by Elsevier Ltd.

mechanics of microtubules

Figure 1. Microtubules as cellular supports. Microtubules are support structures for the cell. When S2 cells are depleted of actin filaments, long, microtubule-filled processes remain. The outline of the cell is clearly seen in differential interference contrast microscopy (DIC) on the left. Fluorescence imaging of GFP-tubulin reveals that long extensions are supported by microtubules. Before actin was depleted, the cells were almost perfectly round.

3.2 biopolymers - energy

mechanics of microtubules

Figure 2. Microtubule structure and dynamics. Microtubules are polymer filaments made from tubulin dimers. The tubulin heterodimer is made of a beta (dark) and alpha (light) subunit. A few hundred dimers bind together to nucleate the polymer, and individual dimers add on to the ends to grow the microtubule. The plus end is the more dynamic and rapidly growing and shrinking end, the minus end is less dynamic.

mechanics of microtubules - cilia

Scanning electron microscope image of lung trachea epithelium. Inside cilia and flagella is a microtubule-based cytoskeleton called the axoneme. The axoneme of primary cilia typically has a ring of nine outer microtubule doublets, and the axoneme of a motile cilium has two central microtubule doublets in addition to the nine outer doublets. The axonemal cytoskeleton acts as a scaffolding for various protein complexes and provides binding sites for molecular motor proteins such as kinesin II, that help carry proteins up and down the microtubules.

daghlian [2006]

22

mechanics of microtubules - flagella

Though eukaryotic flagella and motile cilia are ultrastructurally identical, the beating pattern of the two organelles can be different. In the case of flagella, e.g., the tail of a sperm, the motion is propeller-like. In contrast, beating of motile cilia consists of coordinated back-and-forth cycling of many cilia on the cell surface.

Problem 1

In class, we have assumed microtubules to be solid cylinders with a Young's modulus of $E = 1.9 \cdot 10^9 \text{N/m}^2$ and a radius of approximately $r^{\text{solid}} = 12.5 \text{nm}$. We have calculated their cross section area $A^{\text{solid}} = \pi r^{\text{solid}2}$ to $A^{\text{solid}} = \pi (12.5 \text{nm})^2 = 491 \text{nm}^2$ and their moment of inertia $I^{\text{solid}} = 1/4 \pi r^4$ to $I^{\text{solid}} = 1/4 \pi (12.5 \text{nm})^4 = 19,175 \text{nm}^4$. Actually this was an oversimplification. In reality, microtubules are hollow cylinders. The outer and inner radii have been determined to $r^{\text{outer}} = 14 \text{nm}$ and $r^{\text{inner}} = 11 \text{nm}$.

- 1.1 Calculate the cross section area $A^{\text{hollow}} = \pi [r^{\text{outer}2} - r^{\text{inner}2}]$ of microtubules when considered as a hollow cylinders.
- 1.2 Calculate the moment of inertia $I^{\text{hollow}} = 1/4 \pi [r^{\text{outer}4} - r^{\text{inner}4}]$ of microtubules when considered as a hollow cylinders.
- 1.3 Calculate the radius r^{solid} of an imaginary solid cylinder which would have the same cross section area as microtubules.
- 1.4 Calculate the moment of inertia of I^{solid} of this imaginary solid cylinder of equal cross section area.

homework 01

24

Problem 2

To gain a better understanding of the bending stiffness of microtubules, consider microtubules as cantilever beams of length $L = 5\mu\text{m}$, clamped at the centrosome end and loaded by a point load F at the other end. We are interested in the transverse force F that creates a beam deflection of $w = 1\mu\text{m}$ on the free end.

- 2.1 Compare the forces needed to deform microtubules when considered as hollow cylinders (use the moment of inertia I^{hollow} calculated in the previous problem) with the forces needed to deform an imaginary solid cylinder of equal volume (use the value I^{solid} calculated at the end of the previous problem).
- 2.2 Discuss the results! Why, you think, does nature prefer hollow structures over solid structures?

Hints: To solve this problem, you might need the equation for the Euler Bernoulli beam $EI w_{,xx} - M = 0$ as derived in class. In addition, you need to know that the bending moment for a cantilever beam is $M = [L - x]F$. Combine this equation with the beam equation. You then need to integrate the beam equation twice. To determine the integration constants, you need to use the boundary conditions of a cantilever $w(0) = 0$ and $w'(0) = 0$. Solve the final equation for the force F for the different moments of inertia I^{hollow} and I^{solid} !

Matrix Elasticity Directs Stem Cell Lineage Specification

Adam J. Engler,^{1,2} Shamik Sen,^{1,2} H. Lee Sweeney,¹ and Dennis E. Discher^{1,2,3,4,*}

abstract. microenvironments appear important in stem cell lineage specification but can be difficult to adequately characterize or control with soft tissues. native mesenchymal stem cells are shown here to specify lineage and commit to phenotypes with extreme sensitivity to tissue level elasticity. soft matrices that mimic brain are neurogenic, stiffer matrices that mimic muscle are myogenic, and comparatively rigid matrices that mimic collagenous bone prove osteogenic. during the initial week in culture, reprogramming of these lineages is possible with addition of soluble induction factors, but after several weeks in culture, cells commit to the lineage specified by matrix elasticity, consistent with the elasticity-insensitive commitment of differentiated cell types. inhibition of nonmuscular myosin II blocks all elasticity directed lineage specification - without strongly perturbing many other aspects of cell function and shape. the results have significant implications for understanding physical effects of the in vivo microenvironment and also for therapeutic use of stem cells.

engler, sen, sweeney, discher [2006]

homework 01

27

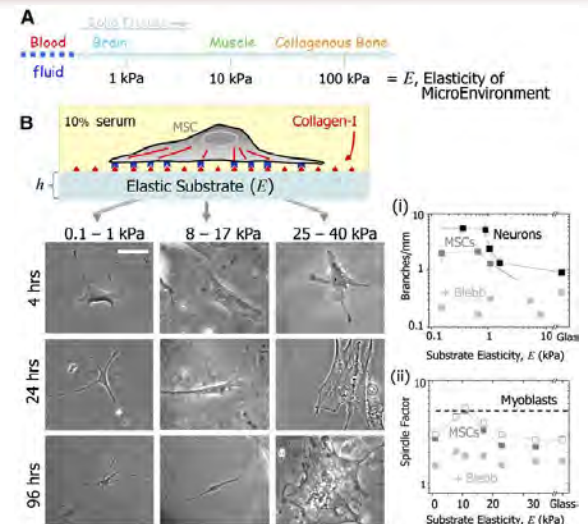

Problem 3

The 2006 manuscript "Matrix elasticity directs stem cell lineage specification" by Engler, Sen, Sweeney, and Discher discusses the importance of mechanical environments during stem cell differentiation. Read the manuscript carefully.

- 3.1 Summarize the manuscript in no more than 150 words.
- 3.2 What are the three cell types discussed in this manuscript? Make a table to compare (i) their elastic stiffnesses, (ii) their microstructural appearances, and (iii) their cellular functions. Feel free to consult other sources of information to complement the table, i.e., cell images from the web, etc.
- 3.3 Figure 1c) given below shows microarray profiling for cells cultured on matrices with different stiffnesses. Compare the first column of each of the three marker sets. Explain the findings in less than 100 words.
- 3.4 For each of the three columns, pick one of the specific markers, look it up, and explain in two or three sentences what its upregulation means for the cell. Example: *MYOD1* is a protein with a key role in regulating muscle differentiation. *MYOD1* is one of the earliest markers of myogenic commitment. It is upregulated in MSCs cultured on 11 kPa stiff gels indicating the lineage specification towards muscle cells.
- 3.5 Discuss the impact of the major findings in this manuscript on stem cell therapies.
