ABSTRACT

In many filamentary structures, such as hydrostatic arms, roots, and stems, the active or growing part of the material depends on contractile or elongating fibers. Through their activation by muscular contraction or growth, these fibers will generate internal stresses that are partially relieved by the filament acquiring intrinsic torsion and curvature. This process is fundamental in morphogenesis but also in plant tropism, nematic solid activation, and muscular motion of filamentary organs such as elephant trunks and octopus arms. Here, we provide a general theory that links the activation of arbitrary fibers at the microscale to the generation of curvature and torsion at the macroscale. This theory is obtained by dimensional reduction from the full anelastic description of three-dimensional bodies to morphoelastic Kirchhoff rods. Hence, it links the geometry and material properties of embedded fibers to the shape and stiffness of the rod. The theory is applied to fibers that are wound helically around a central core in tapered and untapered filaments.

1. Introduction

Filaments are soft slender mechanical structures that are roughly defined by having one dimension much larger than the typical scale of their cross section. Around us, filaments are the strings, ropes, strands, wires, cables, and cords that we encounter in our daily lives. In mechanics, they include beams, strings, strips, ribbons, and rods (Antman, 2005). Passive filaments have fixed material and geometric properties such as length, girth, intrinsic shape, and rigidity. The central problem in the mechanics of these passive objects is to obtain their shapes for given boundary conditions, body forces, and external loads. Due to their particular aspect ratio, the shape of such objects can be captured from their central axis and modeled using a combination of differential geometry of curves and physical balance laws for forces and moments, leading ultimately to the Kirchhoff equations of rod theory (Kirchhoff, 1859; Dill, 1992; Goriely and Tabor, 2000). These equations have been successfully applied to structures as varied in size and functions as DNA, proteins (Benham, 1979; Hoffman et al., 2003; Beveridge et al., 2004; Neukirch et al., 2008a,b), polymers and liquid crystals (Sheley and Ueda, 2000), whips and lassos (McMillen and Goriely, 2002; Brun et al., 2014), and bridge cables (Costello, 1990; Yokota et al., 2001).

By contrast, active filaments share the same slender geometry but have the additional feature of allowing internal remodeling. Many examples of such active structures can be found in the natural world (Goriely, 2017) including neurons (Oliver et al., 2021), anguilliform swimmers (McMillen and Holmes, 2006), roots (Moulton et al., 2020b), stems (Goriely and Neukirch, 2006), tendrils (Goriely and Tabor, 1998), trees (Greenhill, 1881; Guillon et al., 2011), seed pods (Hofhuis et al., 2016), and various tentacles (Kier and Smith, 1985; Kier, 2012; Levinson and Segev, 2010; Shoshani, 1998; Wilson et al., 1991; Moulton et al., 2016).

1 All authors have contributed equally to this work.
In the engineering world, it includes some soft robotic arms (Calisti et al., 2011; Hannan and Walker, 2003; Laschi et al., 2012; Paley and Wereley, 2021; Walker et al., 2005; Jones et al., 2021), liquid crystal elastomers (Goriely et al., 2022) and actuators (de Payrebrune and O’Reilly, 2016; Sano et al., 2021). Internal remodeling can be generated by external fields as in the case of magnetic actuation, by growth during morphogenesis, or by muscular contraction. In most situations, the internal changes can be modeled by the relative change of internal geometry of a volume element along a principal direction. Since the activation is done in a single distinguished direction, we refer to such a volume element as a fiber, and the activation direction as the fiber direction, as shown in Fig. 1. There are now two main questions: What is the intrinsic shape of the filament, for a given activation field, in the absence of body forces and boundary loads? And, what is the shape of the filament when loaded given this intrinsic shape? Here, we will focus on the first question to obtain the active filament formula linking fiber activation to intrinsic curvature and torsion.

Our starting point is the general theory developed in Moulton et al. (2020a) for the problem of determining the curvature, extension, and torsion of a filament for an arbitrary anelastic field. Accordingly, we treat the filament as a morphoelastic solid. This is a continuum that can grow, remodel, support stresses and can be subject to large deformations (Goldstein and Goriely, 2006; Goriely and Moulton, 2010; Goriely, 2017). We use the theory of morphoelasticity, which represents deformations due to elasticity, growth, and remodeling through a multiplicative decomposition of the deformation gradient into elastic and growth tensors (Goriely, 2017).

In the present work, the decomposition is naturally extended to include the activation process, such as mass-preserving contraction or elongation, in the growth tensor. The problem is then to obtain from the specification of a growth tensor representing fiber activation for the full three dimensional problem, the corresponding reduced one-dimensional morphoelastic rod as defined in Lessinnes et al. (2017), Moulton et al. (2012).

2. General set-up

We briefly recall the basic assumptions from Moulton et al. (2020a). We assume that the filament is a three-dimensional tubular body that is allowed to grow and whose shape varies slowly along its axis. The initial structure is stress-free and growth or anelastic activation is defined at every point as a local change of a volume element by the addition, removal, or redistribution of mass. We assume that this filamentary structure deforms into another tubular structure defined by variations along a deformed centerline. The slenderness of this structure introduces naturally a small parameter \( \epsilon \) in the problem that can be used to asymptotically expand the energy of the system. This energy can then be minimized, and the stresses and strains within the section can be obtained explicitly, leaving an energy that can be identified with the energy of a rod. This type of dimensional reduction is related to a large body of work in rational mechanics focused on obtaining systematically reduced models from three-dimensional elasticity (Cimetière et al., 1988; Sanchez-Hubert and Palencia, 1999) and anelasticity (Mora and Müller, 2003; Audoly and Lestringant, 2021; Kohn and O’Brien, 2018; Cicala et al., 2017; Bauer et al., 2019; Kupferman and Solomon, 2014). The emphasis here is not in justifying the reduction but using it to explore the possible shapes that can be created through simple and universal filamentary structures.

2.1. The growth tensor for activation

We consider an initial elastic tubular configuration \( B_0 \subset \mathbb{R}^3 \) with material points \((X, Y, Z) \in B_0\) that can be decomposed as the product \([0,1] \times S\) of a segment of the \( Z\)-axis between 0 and \( L\) and a family of cross-sections \( S_Z\) whose centroids are on the \( Z\)-axis and oriented with the condition

\[ \int_{S_Z} E X \, dX \, dY = \int_{S_Z} EY \, dX \, dY = \int_{S_Z} E XY \, dX \, dY = 0, \]  

(1)

where \( E\) is the Young’s modulus. The typical length scale of each section is \( \mathcal{O}(\epsilon)\), corresponding to a typical or averaged radius, and each cross section is a slowly varying function of the arc length \( Z\), so that, on short scales, the tubular structure is cylindrical.

We consider the deformation \( \chi(X) : B_0 \to B \) from the initial configuration \( B_0 \) to the current configuration \( B \) and model the growth or activation through a tensor \( G \) so that

\[ F = \text{Grad} \chi = AG, \]  

(2)

where the gradient is taken with respect to the \( X \) coordinates and \( A \) is an elastic tensor describing the elastic stretches related to a strain–energy density function \( W = W(A)\). The tensor \( G \) is given with a strictly positive determinant. In the case of fiber activation, the determinant is governed by the Poisson effect of the activating element. In the general description of growth mechanics, the determinant is larger than 1 for growth, and smaller than 1 for shrinkage. For the rest of the paper, we refer to any process with \( G \neq 1 \) as activation. Activation is naturally expressed as a map from the cylindrical coordinates \((r, \theta, Z)\) of the reference configuration to the cylindrical coordinates \((r, \theta, z)\) of the current configuration

\[ G = (1 + G_{ij}) G_0 = G_{ij} e_i \otimes e_j, \quad i \in \{r, \theta, z\}, \quad j \in \{R, \Theta, Z\}, \]  

(3)

where \((e_r, e_\theta, e_z)\) and \((e_R, e_\Theta, e_Z)\) are the usual unit cylindrical basis vectors in the current and reference configuration, respectively, and \( G_{ij} = G_{ij}(r, \theta, Z) \). We restrict our analysis to growth tensors that are small deviations with respect to identity, where the deviation is measured with respect to the small parameter \( \epsilon \):

\[ G = 1 + \epsilon G_0(X). \]  

(4)
Fig. 1. (a), (b) A filamentary structure that contains a field of fibers embedded throughout its body. (c) An infinitesimal volume element with embedded fibers can deform either through growth along the fibers (with $\det(\mathbf{G}) \neq 1$ and $\nu = 0$) or through muscle activation (with $\nu \in [0, 1/2]$ — see text), in which case no new material is produced in the filament body, and the change in size in the directions perpendicular to the activating fiber is due to the Poisson effect with Poisson’s ratio $\nu$.

Fig. 2. We consider a tubular structure in the reference configuration (left) and its deformation in the current configuration (right). The deformed configuration is fully parameterized by the centerline $\mathbf{r}(Z)$ and the deformation of each cross section.
A key assumption of our theory is that we restrict our attention to a particular family of possible deformations, mapping a straight tubular structure to a filament in space $B$ with centerline $\mathbf{r}(Z)$ as shown in Fig. 2. This centerline is the image of a segment of the $Z$-axis defining the centerline of the initial configuration. From this centerline, we define a local director basis $(\mathbf{d}_1(Z), \mathbf{d}_2(Z), \mathbf{d}_3(Z))$ where $\mathbf{r}'(Z) = \zeta \mathbf{d}_1$, $\zeta$ is the axial extension, and ($\cdot$)' denotes derivatives with respect to the material coordinate $Z$. From the director basis, we define the Darboux curvature vector $\mathbf{u} = u_1 \mathbf{d}_1 + u_2 \mathbf{d}_2 + u_3 \mathbf{d}_3$. This vector describes the evolution of the director basis along the filament, satisfying
\[
\mathbf{d}'_i(Z) = \zeta \mathbf{u} \times \mathbf{d}_i. 
\] (5)

The mapping $\chi : B_0 \rightarrow B$ is then written
\[
\chi(X) = \mathbf{r}(Z) + \sum_{i=1}^{3} \varepsilon a_i(\varepsilon R, \Theta, Z) \mathbf{d}_i(Z),
\] (6)
where the reactive strains $a_i$ correspond to deformations of the sections and are to be determined; these satisfy $a_i(0,0,Z) = 0$ so that the $Z$-axis maps to the centerline $\mathbf{r}(Z)$. The particular form (6) expresses the deformation of a tubular body in terms of its centerline and director basis. We note that, since the section has a typical radius $\varepsilon$, the variable $R$ is an order 1 quantity. Taking $\zeta = 1 + \varepsilon \zeta$, the deformation gradient $\mathbf{F} = F_{ij}\mathbf{d}_j \otimes \mathbf{e}_i$, $i \in \{1,2,3\}$, $j \in \{ R, \Theta, Z \}$ is then given by
\[
\mathbf{F} = \begin{bmatrix}
    a_{1R} & \frac{1}{2} a_{1\Theta} & \varepsilon (1 + \varepsilon \zeta) (u_3 a_1 - a_3) \\
    a_{2R} & \frac{1}{2} a_{2\Theta} & \varepsilon (1 + \varepsilon \zeta) (u_1 a_2 - a_1) \\
    a_{3R} & \frac{1}{2} a_{3\Theta} & (1 + \varepsilon \zeta) (1 + \varepsilon (u_2 a_3 - u_3 a_2))
\end{bmatrix}. 
\] (7)

Next, we consider a continuum with a distinguished direction that we call a fiber. Whereas we utilize a model for a material containing fibers that can be activated, it is worth noting that, in our model, the material does not actually contain physical fibers within a matrix. Rather, we assume that the density of fibers is large enough so that they can be represented, locally, by a vector field $\mathbf{m}$, as shown in Fig. 3. In cylindrical coordinates, this arbitrary fiber direction $\mathbf{m}$ is described by two angles $\alpha$ and $\beta$:
\[
\mathbf{m} = \sin \alpha \sin \beta \ \mathbf{e}_R + \sin \alpha \cos \beta \ \mathbf{e}_\Theta + \cos \alpha \ \mathbf{e}_Z. \quad a, \beta \in [-\pi/2, \pi/2].
\] (8)

Helical fibers are tangent to a cylinder centered around the axis and are therefore prescribed by $\beta = 0$ and $\alpha \in [-\pi/2, \pi/2]$ with limiting cases of a hoop fiber at $\alpha = +\pi/2$ and an axial fiber at $\alpha = 0$. A right-handed helical fiber is given by $0 < \alpha < \pi/2$ and a left-handed helical fiber is specified by $-\pi/2 < \alpha < 0$. Sectional fibers lie in the cross-section and are characterized by $\alpha = \pi/2$, with radial fibers given by $\beta = \pi/2$ and, in the limit $\beta = 0$, we recover hoop fibers, as before.

Since we are only considering elongation or contraction along this fiber, $\mathbf{m}$ must be an eigenvector of the tensor $\mathbf{G}$ with eigenvalue $g$. Similarly, the perpendicular vector $\mathbf{m}_\perp = \cos \beta \ \mathbf{e}_R - \sin \beta \ \mathbf{e}_\Theta$ and $\mathbf{m}_\perp' = \mathbf{m} \times \mathbf{m}_\perp$ are also eigenvectors of $\mathbf{G}$:
\[
\mathbf{G} \cdot \mathbf{m} = g \mathbf{m}, \quad \mathbf{G} \cdot \mathbf{m}_\perp = \delta g_3 \mathbf{m}_\perp, \quad \mathbf{G} \cdot \mathbf{m}_\perp' = \delta g_3' \mathbf{m}_\perp'.
\] (9)

We consider two cases: growth and activation (see Fig. 1c). In the growth case, there is a change of length of the fiber $\delta = 1 + \varepsilon g(R, \Theta)$ that is not accompanied by a change in the transverse direction and $\delta = \delta_3 = 1$. For active fibers, the extension (contraction) of the fiber generates a contraction (extension) in the transverse directions, with any change in volume due to the action of $g$ described by the Poisson’s ratio. Therefore, for small $\varepsilon$, we have $\delta_3 = \delta_3' = 1 - \varepsilon g(R, \Theta)$ and $\delta = 1 + \varepsilon g(R, \Theta)$, where $\varepsilon$ is the Poisson’s ratio. We see that both cases can be combined by taking either $\nu = 0$ for growth and $\nu \in [0,1/2]$ for an active fiber (in the case $\nu = 0$, there is no distinction between an active fiber and growth as the material extends without lateral contraction). We emphasize that $a$, $\beta$ and $g$ may be functions of $R$, $\Theta$, and, possibly, slowly varying functions of $Z$. Combining both cases, the growth tensor in cylindrical coordinates is
\[
\mathbf{G} = 1 + \varepsilon g \begin{bmatrix}
    (1 + \nu) \sin^2 \alpha \sin^2 \beta - \nu & (1 + \nu) \sin^2 \alpha \cos \beta \cos \beta & (1 + \nu) \sin \alpha \cos \alpha \sin \beta \\
    (1 + \nu) \sin^2 \alpha \sin \beta \cos \beta & (1 + \nu) \sin^2 \alpha \sin^2 \beta - \nu & (1 + \nu) \sin \alpha \cos \alpha \cos \beta \\
    (1 + \nu) \sin \alpha \cos \alpha \sin \beta & (1 + \nu) \sin \alpha \cos \alpha \cos \beta & \frac{1}{2}(1 - \nu + (1 + \nu) \cos 2\alpha)
\end{bmatrix}.
\] (10)

2.2. The energy density

We assume that the growing material is a compressible hyperelastic material with strain–energy density $\mathcal{W} = \mathcal{W}(\mathbf{A})$. The total energy of the system is
\[
\mathcal{W} = \int_{B_0} \mathcal{W}(\mathbf{A}) \det \mathbf{G} \ dX dY dZ,
\] (11)
which can be written in terms of $\mathbf{F}$ and $\mathbf{G}$ as
\[
\mathcal{W} = \int_{B_0} \mathcal{V}(\mathbf{F}^{-1}, \mathbf{G}) dX dY dZ, \quad \mathcal{V} = \mathcal{W}(\mathbf{F}^{-1}) \det \mathbf{G}.
\] (12)

The problem is then to minimize this energy for a given $\mathbf{G}$ over the set of allowable deformations gradients $\mathbf{F}$ considered above. In cylindrical coordinates, the energy can be written
\[
\mathcal{W} = \varepsilon^2 \int_0^L dZ \int_S \mathcal{V}(\mathbf{F}^{-1}, \mathbf{G}) R dR d\Theta.
\] (13)
We proceed by expanding the inner variables $a_i$, with the auxiliary energy density taking the form

$$V(FG^{-1}, G) = V_0 + \varepsilon^2 V_2 + \mathcal{O}(\varepsilon^3),$$

(14)

where each $V_i = V(a^{(i)}_1, a^{(i)}_2, a^{(i)}_3, a^{(i)}_r, a^{(i)}_\theta, a^{(i)}_{2r}, a^{(i)}_{2\theta}, a^{(i)}_{3r}, a^{(i)}_{3\theta}).$ The Euler–Lagrange equations then become

$$\frac{\partial}{\partial R} \frac{\partial V_i}{\partial a^{(k)}_j} + \frac{1}{R} \frac{\partial V_i}{\partial a^{(k)}_j} + \frac{\partial}{\partial \theta} \frac{\partial V_i}{\partial a^{(k)}_j} \frac{\partial a^{(k)}_j}{\partial \theta} = 0, \quad j = 1, 2, 3, \quad k = 0, 1,$$

(15)

with the appropriate natural boundary conditions.

To lowest order, the solution of the Euler–Lagrange equations is given by

$$a^{(0)} = R(\cos \Theta, \sin \Theta, 0).$$

(16)

---

Fig. 3. (a) We consider arbitrary fibers characterized by angles $\alpha = a(R, \Theta)$ and $\beta = b(R, \Theta)$ with respect to the section. (b) Representative fiber architectures for constant $\alpha$ and $\beta$: axial (top-left), helical (top-right), hoop (bottom-left), and radial (bottom-right) fibers.
To order $O(\varepsilon)$, the Euler–Lagrange equations are identically satisfied. To order $O(\varepsilon^2)$, the solution for the reactive strains is

\[ a_1^{(1)} = -\frac{iR}{4(\lambda + \mu)} (R\mu \sin 2\theta - R\mu \cos 2\theta + 2\zeta \cos \theta) + f_1(R, \Theta), \]

\[ a_2^{(1)} = -\frac{iR}{4(\lambda + \mu)} (R\mu \cos 2\theta + R\mu \sin 2\theta - 2\zeta \sin \theta) + f_2(R, \Theta), \]

\[ a_3^{(1)} = \omega(R, \Theta) + u_3\phi(R, \Theta), \]

where $f_{1,2}$ are functions that only enter in the so-called reactive part of the energy and are not needed to compute the moduli and intrinsic curvature.

The function $\phi(R, \Theta)$ is the classic warping function and is a solution of the Neumann problem for the Laplace equation:

\[ \Delta \phi = 0, \quad \mathbf{X} \in S \]

\[ \mathbf{n} \cdot \nabla \phi = -R \mathbf{n} \mathbf{e}_3, \quad \mathbf{X} \in \partial S. \]

where $\mathbf{n}$ is the unit outward normal vector to the cross section boundary $\partial S$.

The function $\omega(R, \Theta)$ is a new function that we call the torsion function. It is given by the solution of the Poisson equation with a null Neumann condition:

\[ \Delta \omega = -2R(1 + \nu) \left[ \sin a \cos a (R \xi R \sin \beta + \xi a \cos \beta) + g (R \xi R \sin^2 a \sin \beta + a \xi \cos(2a) \cos \beta + R \xi R \cos^2 a \sin \beta - \rho_\beta \sin a \cos a \sin \beta \right] \]

\[ \mathbf{n} \cdot \nabla \omega = 0, \quad \mathbf{X} \in \partial S. \]

With the solution for the reactive strains, the energy takes the form

\[ \mathcal{E} = \varepsilon^4 \int_0^L \int_S \mathcal{H}_0 (\mathbf{Z}, \mathbf{a}^{(1)}; u_1, u_2, u_3, \xi) \, dR \, d\Theta + O(\varepsilon^5). \]

Since the strain–energy density is isotropic and its contribution in the expression for $V$ includes at most quadratic terms in the strains, we can use without loss of generality the quadratic approximation of $W$:

\[ W = \frac{1}{2} \left[ \mu \left( \text{tr} (\mathbf{H}^T \mathbf{H}) + \text{tr}(\mathbf{H}^2) \right) + \lambda \text{tr}(\mathbf{H})^2 \right]. \]

where $\mathbf{H} = \mathbf{A} - I$ and $\mu$, $\lambda$ are the Lamé parameters. After integration, up to order $O(\varepsilon^4)$, we find

\[ \mathcal{E} = \frac{1}{2} \int_0^L \int_S K_0(\xi - \xi_0)^2 + K_1(u_1 - \bar{u}_1)^2 + K_2(u_2 - \bar{u}_2)^2 + K_3(u_3 - \bar{u}_3)^2 \, dZ. \]

Here we have used $\xi = (\xi - 1)/R_0$, where $R_0$ is the typical scale of the cross section. We recover the classic extensional, bending, and torsional stiffness coefficients of rod theory

\[ K_0 = \int_S ER \, dR \, d\Theta. \]

\[ K_1 = \int_S ER^2 \sin^2 \Theta \, dR \, d\Theta. \]

\[ K_2 = \int_S ER^2 \cos^2 \Theta \, dR \, d\Theta. \]

\[ K_3 = \int_S \mu \left( R^2 + 2R \delta_{\beta} \phi + \frac{1}{R} \delta^2_{\beta} \phi + R \phi \right) \, dR \, d\Theta. \]

where $E = \mu(\lambda + 2\mu)/(\lambda + \mu)$ is the Young’s modulus which can be taken as a function of position. If $E$ and $\mu$ are constant, we recover

\[ K_0 = EA, \quad K_1 = EI_1, \quad K_2 = EI_2, \quad K_3 = \mu J. \]

where $A$ is area of the cross section whereas $I_{1,2}$ are its second moments of area, and $J$ is a parameter that depends only on the cross-sectional shape and the warping function. In addition, we define

\[ H_0 = \frac{1}{2} \int_S E(1 - \nu + (1 + \nu) \cos 2\alpha) g \, R \, dR \, d\Theta. \]

\[ H_1 = \frac{1}{2} \int_S ER^2(1 - \nu + (1 + \nu) \cos 2\alpha) g \, \sin \Theta \, dR \, d\Theta. \]

\[ H_2 = \frac{1}{2} \int_S ER^2(1 - \nu + (1 + \nu) \cos 2\alpha) g \, \cos \Theta \, dR \, d\Theta. \]

\[ H_3 = \frac{1}{2} \int_S \frac{E}{\nu + 1} \left( E(1 + 2\sin(2\alpha)) ((R^2 + f_0) \cos \beta + g \phi R \sin \beta) \right) \]
\[
- \frac{\omega a (\phi \theta + R^2)}{R} - R \omega_k \phi_R \right) \, dR \, d\theta. \tag{35}
\]

From these quantities, we extract the intrinsic extension and curvatures:
\[
\ddot{\zeta} = 1 + H_0/K_0, \quad \ddot{u}_1 = H_1/K_1, \quad \ddot{u}_2 = -H_2/K_2, \quad \ddot{u}_3 = H_3/K_3. \tag{36}
\]

We refer to the last three sets of definitions for $H_i$, $K_i$, and $\ddot{u}_i$ as the *active filament formulas* as they describe in a fundamental way how curvatures are related to *internal* stresses induced by growth or activation. These formulas are named in honor of the fundamental *helical spring formulas* obtained by Thomson and Tait that relate the curvatures to *external* stresses (Thomson and Tait, 1867; Goriely et al., 2012).

### 3. Particular case of a circular cross-section

The expressions above simplify greatly if we consider a circular cross-section of radius $R_0$. In that case, the stiffnesses $K_i$ have been tabulated for different types of inclusions and the appropriate formulas can be found in textbooks for different profiles of $E$. For a uniform material with no variations of $E$, we have:
\[
K_0 = E \pi R_0^2, \quad K_1 = E \pi R_0^4/4, \quad K_2 = E \pi R_0^4/4, \quad K_3 = E \pi R_0^4/4. \tag{37}
\]

More interestingly, the warping function is identically zero and, since $\omega$ is periodic in $\Theta$, it will not contribute. We then obtain an explicit expression in terms of the given functions $g = g(R, \Theta)$, $a = a(R, \Theta)$, $\beta = \beta(R, \Theta)$, and the material parameters $v$ and $E$:

\[
H_0 = \frac{1}{2} \int_0^{R_0} R \, dR \int_0^{2\pi} Eg(1 - v + (1 + v) \cos 2\alpha) \, d\Theta, \tag{38}
\]

\[
H_1 = \frac{1}{2} \int_0^{R_0} R^2 \, dR \int_0^{2\pi} Eg(1 - v + (1 + v) \cos 2\alpha) \sin \Theta \, d\Theta, \tag{39}
\]

\[
H_2 = \frac{1}{2} \int_0^{R_0} R^2 \, dR \int_0^{2\pi} Eg(1 - v + (1 + v) \cos 2\alpha) \cos \Theta \, d\Theta, \tag{40}
\]

\[
H_3 = \frac{1}{2} \int_0^{R_0} R^2 \, dR \int_0^{2\pi} Eg \beta \sin 2\alpha \, d\Theta. \tag{41}
\]

#### 3.1. Ring solution

We first consider the case of a ring of helical fibers $R \in [R_1, R_2]$ with constant moduli in a cylinder of radius $R_0$. We further assume that the helical structure is created initially by a uniform twist, and thus it satisfies the relationship

\[
\tan a = \frac{\tan a_2}{R_2}, \tag{42}
\]

where $a_2 \in ]-\pi/2, +\pi/2[$ is the helical angle on the cylinder of radius $R_2$. Assuming that each cylinder contains physical helical fibers, the activation $g$ on two different sections is related to the angle $a_2$ such that

\[
g(R, \Theta) = \gamma(\Theta - \frac{Z}{R} \tan a) = \gamma(\Theta - \frac{Z}{R_2} \tan a_2). \tag{43}
\]

The functions $H_i$ can then be expressed in terms of the first three Fourier coefficients of $\gamma$

\[
a_0 = \frac{1}{\pi} \int_0^{2\pi} \gamma(\Theta) \, d\Theta, \quad a_1 = \frac{1}{\pi} \int_0^{2\pi} \gamma(\Theta) \cos \theta \, d\Theta, \quad b_1 = \frac{1}{\pi} \int_0^{2\pi} \gamma(\Theta) \sin \theta \, d\Theta, \tag{44}
\]

as follows

\[
H_0 = \frac{E \pi}{2} \delta_0 a_0, \tag{45}
\]

\[
H_1 = -\frac{E \pi}{3} \delta_1 A \sin(\varphi - \frac{Z}{R_2} \tan a_2), \tag{46}
\]

\[
H_2 = -\frac{E \pi}{3} \delta_2 A \cos(\varphi - \frac{Z}{R_2} \tan a_2), \tag{47}
\]

\[
H_3 = \frac{E \pi}{2(1+v)} \delta_3 a_0, \tag{48}
\]

where we defined $A$ and $\varphi$ through $a_1 = A \cos \varphi$, $b_1 = -A \sin \varphi$ and

\[
\delta_0 = (v + 1)R_2^2 \cot^2 a_2 \log \left( \frac{R_2^2 \sec^2 a_2}{R_1^2 \tan^2 a_2 + R_2^2} \right) + \nu \left( R_1^2 - R_2^2 \right), \tag{49}
\]

\[
\delta_1 = \delta_2 = (R_1 - R_2) \left( (v + 1)R_2^2 + R_2 R_1 + R_1^2 \right) - 3(v + 1)R_2^2 \cot^3 a_2 \]

\[
+ 3(v + 1)R_2^2 \cot^3 a_2 \arctan \left( \frac{R_1 \tan a_2}{R_2} \right) - 3a_2(v + 1)R_2^2 \cot^3 a_2, \tag{50}
\]
\[ \delta_3 = -(1 + \nu)R_2 \cot a_2 \left( R_1^2 - R_2^2 + R_3^2 \cot^2 a_2 \log \left( \frac{2R_3^2}{(R_2^2 - R_1^2) \cos 2a_2 + R_1^2 + R_2^2} \right) \right). \] (51)

From these expressions, we compute the intrinsic stretch and curvatures:

\[ \hat{\varepsilon} = 1 + \frac{\alpha_1 \delta_1}{2R_0^2}, \] (52)
\[ \hat{u}_1 = -\frac{4\alpha_0}{3R_0^4} \sin(\varphi - \frac{Z}{R_2} \tan a_2), \] (53)
\[ \hat{u}_2 = \frac{4\alpha_0}{3R_0^4} \cos(\varphi - \frac{Z}{R_2} \tan a_2), \] (54)
\[ \hat{u}_3 = \frac{2\alpha_0}{R_0^2} a_0. \] (55)

These intrinsic curvatures have the familiar form \( \hat{u} = (\zeta k \sin \phi, \zeta k \cos \phi, \zeta \tau + \phi') \) (Goriely, 2017, p. 103) from which we obtain the intrinsic Frenet curvature and torsion:

\[ \hat{k} = \frac{4}{3\zeta^2 R_0^4} |\delta_1| A, \] (56)
\[ \hat{\tau} = \frac{1}{\zeta} \left( \tan a_2 \frac{R_2}{R_1} + \frac{2\alpha_0 a_0}{R_0^2} \right). \] (57)

Note that we must include the factor \( \zeta \) here to take into account the change of length in the rod due to activation. A few comments are in order:

- In the case of incompressible activation (\( \nu = 1/2 \)), the factor \( (1 - \nu + (1 + \nu) \cos 2\alpha) \) that appears in (38)–(40) is \( \delta_1 = 1 + 3 \cos 2\alpha \). It vanishes at the magic angle (Goriely, 2017) given by \( \alpha \approx \pm 54.73 \) degrees. Therefore, we can design a system with fiber angles close to that particular angle so that \( \delta_1 = \delta_2 = 0 \). For this system there is no curvature induced by the activation of the fibers (Goriely and Tabor, 2013). The absence of extension is well known in the theory of McKibben actuators. The absence of curvature at that angle seems to be new and unexpected. It will be further analyzed in the next section.

- The contribution to the curvature from activation is specified by the amplitude of the first Fourier components \( A = \sqrt{a_1^2 + b_1^2} \). This amplitude can be controlled by a function \( \gamma \) that can be either continuous or discrete.

- The activation of a ring sector with \( A \delta_1 \neq 0 \) leads in general to an intrinsic helical centerline since both curvature and torsion are constant.

- Right-handed helical fibers can lead to a left-handed helical shape if \( -a_0 \) is sufficiently large, which requires average contraction of the fiber on the ring. Any extension of the fibers will lead to a shape with the same handedness.

- We emphasize again that the contribution of any activation function \( \gamma(\theta) \) only enters through its first three Fourier coefficients. Hence, on a ring, there are at most three independent degrees of freedom dictating the curvatures.

### 3.2. Ring solution with piecewise constant and uniform activation

We further constrain the system by assuming that activation is uniform along \( Z \) and piecewise constant along \( \theta \), as shown in Fig. 4, and take \( R_2 = R_0 \). Let \( B(x; x_0, \sigma) \) be the real 2\( \pi \)-periodic function that is zero everywhere except in the interval \( [x_0 - \sigma/2, x_0 + \sigma/2] \) where it is equal to one. Then, our activation function has \( N \) equally spaced helical activators in the ring:

\[ \gamma(\theta) = \sum_{i=0}^{N-1} \gamma_{i+1} B(\theta; \theta_0 + \frac{2\pi i}{N}, \sigma), \] (58)

where \( \sigma \leq 2\pi/N \) to avoid overlap. The corresponding Fourier coefficients are:

\[ a_0 = \frac{\sigma}{\pi} \sum_{i=1}^{N} \gamma_i, \] (59)
\[ a_1 = 2 \frac{\sin(\sigma/2)}{\pi} \sum_{i=0}^{N-1} \gamma_{i+1} \cos(\theta_0 + \frac{2\pi i}{N}), \] (60)
\[ b_1 = 2 \frac{\sin(\sigma/2)}{\pi} \sum_{i=0}^{N-1} \gamma_{i+1} \sin(\theta_0 + \frac{2\pi i}{N}). \] (61)

We observe that there are only three independent variables for activation: \( a_0, a_1, \) and \( b_1 \). Therefore, one does not need more than three independent activators, i.e., the choice \( N = 3 \) is sufficient in terms of their relative effect, and their angular extent can be adjusted to increase the magnitude of the response. The variable \( \theta_0 \) is a phase that is used to adjust the initial position of the activator. It can be set to zero without loss of generality by assuming that one of the filament ends can be rotated arbitrarily. Therefore, for the rest of our analysis, we set \( \theta_0 = 0 \).

In order to understand the possible material and activation controls, we consider two extreme cases.
Fig. 4. Schematic representation of piecewise constant activation distributions \( \gamma(\theta) \) for the case of a single-ring geometry (a), and a geometry with \( M \) concentric rings (b). Red-filled regions correspond to \( \gamma \neq 0 \), while all other regions are not activated. (c) A representative three-dimensional structure of an activated filament showing how the active regions twine around the main axis based on the angle of the fibers.

3.2.1. Curvature without torsion

We first look at the possibility of creating intrinsic curvature with helical fibers \( (\alpha_2 \neq 0) \) without intrinsic torsion. From the relation (57), we see that it requires a combination of material properties and activation. Indeed, \( \delta_3 \) has the same sign as \( \tan \alpha_2 \). Hence, zero torsion can only occur if \( a_0 \) is negative, which implies contraction on average, and requires

\[
a_0 = -\frac{R_0^3}{2\delta_3} \tan \alpha_2.
\] (62)

In addition, we need \( A = \sqrt{a_1^2 + b_1^2} \) to be non-vanishing, which implies that all the \( \gamma_i \) cannot be equal to each other. We show in Fig. 5 that zero torsion is only possible for small values of the helical angle, as higher values would require unrealistically large values of \( -\gamma_i \).

3.2.2. Twist without curvature

In the absence of curvature, there can be no torsion. Thus, the complementary problem to the problem of curvature without torsion is twisting a rod in the absence of curvature. There are two ways that can be used to remove curvature from the system.

First, by symmetry, we have that \( a_1 = b_1 = 0 \) if \( \gamma_i = \gamma \) for all \( i \). In this case, the system does not develop any curvature but only twist.

Second, we can design the structure so that \( \delta_1 = 0 \) for all activations. Indeed for given radii \( R_1 \) and \( R_2 = R_0 \), we can choose the angle \( \alpha_2 \) so that \( \delta_1 = 0 \) as shown in Fig. 6. This can only happen for a narrow range of angles between \( \alpha_2^* \leq \alpha_2 \leq \alpha_2^{**} \), where \( \alpha_2^* = \arccos(-1/3)/2 \) is the magic angle and \( \alpha_2^{**} \) is the solution of \( 1 = -9a_2 \cot^3 \alpha_2 + 9 \cot^2 \alpha_2 \).
4. Multiple rings

We can design a filamentary structure with multiple rings as shown in Fig. 4. In this case, each new ring contributes to the intrinsic curvatures additively. Denoting by a superscript \( (i) \) a quantity attached to the \( i \)th ring from 1 to \( M \), we simply have:

\[
\hat{\xi} = 1 + \frac{1}{2R_0} \sum_{i=1}^{M} \delta_0^{(i)} \psi_0^{(i)},
\]

\[
\hat{u}_1 = -\frac{4}{3R_0} \sum_{i=1}^{M} A^{(i)} \delta_1^{(i)} \sin(\phi^{(i)}) - \frac{Z}{R_0^2} \tan \alpha_2^{(i)},
\]

\[
(63)
\]

\[
(64)
\]
Fig. 7. Domain geometry and helical fiber architecture in the tapered filament case: a three-dimensional view (left), an orthographic side view (top-right), and a cross-sectional slice (bottom-right). Representative fibers are shown on two surfaces of revolution $R = R_1(Z)$, $R = R_0 R_2(Z)/R_0(0)$, where $R_1(Z) = R_0 f(Z)$ is some arbitrary tapering profile. On $R = R_1(Z)$, $\tilde{\alpha}_2$ is constant by construction, while the tapering angle on $R = R_2$, i.e., $\phi_2$, is a function of $Z$ for a general $R_1(Z)$.

\[
\hat{\mathbf{m}} = \sin \tilde{\alpha} \sin \tilde{\beta} \mathbf{e}_R + \sin \tilde{\alpha} \cos \tilde{\beta} \mathbf{e}_\theta + \cos \tilde{\alpha} \mathbf{e}_Z, \quad \tilde{\alpha}, \tilde{\beta} \in ]-\pi/2, +\pi/2[
\]

is mapped to

\[
\mathbf{m} = R \cdot \hat{\mathbf{m}} = (\sin \tilde{\alpha} \sin \tilde{\beta} \cos \phi - \cos \tilde{\alpha} \sin \phi) \mathbf{e}_R + \sin \tilde{\alpha} \cos \tilde{\beta} \mathbf{e}_\theta + (\sin \tilde{\alpha} \sin \tilde{\beta} \sin \phi + \cos \tilde{\alpha} \cos \phi) \mathbf{e}_Z.
\]
These angles now have the same interpretation as the ones given in Fig. 3. For instance, an axial fiber in the tapered case lies in a plane that contains the $Z$-axis and is characterized by $\bar{a} = \bar{\beta} = 0$, and so on. Using these new angles, we can compute the two angular functions that enter the active filament formulas:

$$\cos 2\alpha = \sin 2\bar{a} \sin \bar{\beta} \sin 2\phi - \sin^2 \bar{a} \left( \sin^2 \bar{\beta} \cos 2\phi + \cos^2 \bar{\beta} \right) + \cos^2 \bar{a} \cos 2\phi,$$

$$\cos \beta \sin 2\alpha = 2 \sin \bar{a} \cos \bar{\beta} \left( \sin \bar{a} \sin \bar{\beta} \sin \phi + \cos \bar{a} \cos \phi \right).$$

(70) (71)

5.1. Curvature and torsion in tapered filaments

In the case of the ring solution, we utilize a uniform twist relationship for the tapered fiber field akin to (42), such that

$$\tan \frac{\bar{\alpha}}{R} = \tan \frac{\bar{\alpha}_2}{R_2} = c_{\alpha}, \quad \tan \frac{\phi}{R} = \tan \frac{\phi_2}{R_2} = c_{\phi},$$

(72)

where $c_{\alpha} = c_{\alpha}(Z)$, $c_{\phi} = c_{\phi}(Z)$ are introduced for notational brevity. For such a construction of a tapered fiber field, the activation function $g$ can be written as $g(R, \Theta) = \gamma(\Theta - \Theta_0)$, where the angular shift function $\Theta$ is given by

$$\hat{\Theta}(R, Z) = \tan \frac{\bar{\alpha}_2}{Z} \int_0^Z \sqrt{1 + \left[ R^0 f'(s) \right]^2} \, ds,$$

(73)

and $R^0 \in [R_1(0), R_2(0)]$ is the radius at which a given activated fiber originates at $Z = 0$. Under the assumption of a slow tapering profile $f(Z)$, the variation of $\Theta$ with respect to $R^0$ is negligible. Thus, we can perform the substitution $R^0 \leftarrow R_2(0)$ to obtain an approximate form $\hat{\Theta}_2(Z) = \hat{\Theta}(R_2(0), Z)$ of the angular shift, which depends only on $Z$. Then, substituting $g(R, \Theta) = \gamma(\Theta - \Theta_2)$ into (38)-(41) yields

$$H_0 = \frac{E \pi}{4} \delta_0 a_0,$$

$$H_1 = -\frac{E \pi}{6} \delta_1 A \sin(\phi - \hat{\Theta}_2),$$

$$H_2 = \frac{E \pi}{6} \delta_2 A \cos(\phi - \hat{\Theta}_2),$$

$$H_3 = \frac{E \pi}{6} \delta_3 a_0,$$

(74) (75) (76) (77)

where $\delta_0, \delta_1, \delta_2, \delta_3$ are functions of $c_{\alpha}$, $\bar{\beta}$, $c_{\phi}$, $R_1$, $R_2$, $\nu$, and all other quantities are defined as before. In the case of tangentially helical fibers ($\bar{\beta} = 0$), $\delta_3$ reduce to

$$\delta_0 = 2 \left( R_1^2 - R_2^2 \right) \nu - \frac{2(1 + \nu)}{c_{2}^{2} - c_{2}^{2}} \log \left( \frac{1 + R_1^2 c_{2}^{2}}{1 + R_2^2 c_{2}^{2}} \right)$$

$$\delta_1 = \frac{2}{c_{2}^{2} c_{3}^{2}} \left( 3(1 + \nu) \left[ \arctan \left( R_1 c_{\phi} \right) - \arctan \left( R_2 c_{\phi} \right) \right) c_{\phi} + \left( R_1^2 - R_2^2 \right) v c_{2}^{2} c_{\phi} c_{\nu} \right.$$

$$\left. - c_{\phi} \left( 3(1 + \nu) \left[ \arctan \left( R_1 c_{\phi} \right) - \arctan \left( R_2 c_{\phi} \right) \right) + \left( R_1^2 - R_2^2 \right) v c_{2}^{2} \right] \right),$$

$$\delta_3 = \frac{3}{c_{2}^{2} c_{3}^{2}} \sqrt{c_{2}^{2} - c_{2}^{2}} \left[ \left( T(-R_1) + T(R_1) - T(-R_2) - T(R_2) \right) c_{2}^{2} + 2 c_{\phi} \left( -S(R_1) + S(R_2) \right) \right].$$

(78) (79) (80)

where

$$T(R) = \arctan \left( \frac{c_{\phi} + i c_{2}^{2} R}{S(R)} \right), \quad S(R) = \sqrt{\left( c_{2}^{2} - c_{2}^{2} \right) \left( 1 + c_{2}^{2} R^2 \right)}.$$
5.2. Activation in non-tapered and tapered filaments

We now compile the main results to inform the comparison of configurations resulting from activation in non-tapered and tapered filaments. In particular, as shown in Fig. 9, we consider a multi-ring geometry in both cases. The first ring contains axial fibers ($\hat{\alpha}_2(1) = \hat{\beta}_2(1) = 0$), and the second ring consists of helical fibers ($\hat{\alpha}_2(2) \neq 0$, $\hat{\beta}_2(2) = 0$), with $\phi_2(0) = 0$ and $\phi_2(1) > 0$ in the non-tapered and tapered scenarios, respectively. In such a setup, the first ring enables direct curvature control, while the activation of the second ring promotes torsion. Generally, these effects are not decoupled when both rings are activated simultaneously, so special care needs to be taken in designing the activation patterns for a desired configuration to be attained.

The same activation distributions, $\gamma_1(\theta), \gamma_2(\theta)$ (Fig. 9e), are prescribed in the corresponding rings in both geometries, for the comparison to be meaningful. Moreover, the initial ring thicknesses $R_i(0) - R_i(1)$ are set to be the same in both cases, so that the activation magnitudes are comparable as well. In order to ensure that the outer boundary of the first ring and the inner boundary of the second ring coincide at all $Z$, $R_1(0) = R_2(0)$ and $c_3(1) = c_3(2)$ at all $Z$, for some $\phi_2(2)$. For simplicity, the tapering profile $f(Z)$ is chosen to be linear, but the same analysis can be readily applied for an arbitrary form of $f(Z)$.

Activation of the tapered filament (Fig. 9g) results in a notably more elaborate configuration, as compared to the deformed shape of the non-tapered geometry (Fig. 9f). The variation in the magnitude of curvature and torsion is considerably larger in the tapered case, as expected based on the prior analysis in Fig. 8, but it is now confirmed for the multi-ring scenario. Further, the tapered configuration is more compact in space due to the same activation magnitudes being applied in rings of decreasing thickness, which induces significant curvature and torsion especially towards the end of the filament.

From a practical perspective, the tapered filament assumes a morphology similar to a biological arm during a grappling motion, such as an elephant trunk wrapping around a tree branch. The development of a physiologically functional configuration upon activation in the tapered case might point to the mechanical role of tapering in biological filaments.
Fig. 9. Comparison of configurations developed upon activation in the non-tapered and tapered cases. A multi-ring geometry with rings of equal thickness is assumed in both (a) the non-tapered reference configuration, and (d) the tapered reference configuration. (b), (c) Both domains contain axial fibers embedded in the first ring and helical fibers in the second ring. (e) The same activation distributions $\gamma^{(1)}(\theta)$, $\gamma^{(2)}(\theta)$ are simulated in both the non-tapered and tapered scenarios. Imposing the activation results in configurations (f) and (g) for the non-tapered and tapered cases, respectively. Parameters for the non-tapered reference geometry: $R^{(1)}_1 = 0.7$, $R^{(2)}_1 = R^{(1)}_2 = 1.1$, $R^{(2)}_3 = 1.5$, $L = 30$, $a^{(1)}_2 = \pi/4$, $a^{(2)}_2 = \beta^{(1)} = \beta^{(2)} = 0$; for the tapered reference geometry: $R^{(1)}_1(0) = 1.8$, $R^{(2)}_1(0) = R^{(1)}_2(0) = 2.2$, $R^{(2)}_3(0) = 2.6$, $L = 30$, $a^{(1)}_2 = \pi/4$, $\phi^{(2)}_2 = \pi/40$, $\tilde{a}^{(1)}_2 = \tilde{\beta}^{(1)} = \tilde{\beta}^{(2)} = 0$. Material parameters were chosen to be $E = 1$, $\nu = 0.5$ in both cases.

6. Conclusion

Active filaments are one-dimensional structures that remodel internally. Here, we have assumed that the lone source of this remodeling process is a fiber activation field given at any point in the material, specifying extension or contraction in a given direction. The case of activation by growth or muscular contraction are both taken into account through the specification of a Poisson-like ratio for the extending fiber. This fiber activation is not the most general case of activation as, in principle, a full anelastic tensor could be specified at each point. Yet, from a modeling point of view, these fiber-driven active structures are ubiquitous and universal. Within this framework, we derived the so-called active filament formulas linking fiber stretch and orientation to the intrinsic curvatures generated by the remodeling process.

We further restricted our attention to the case of filaments with circular cross sections and ring solutions for rope-like structures. In these materials, the orientation of the fiber is slaved to the orientation of the active material. As the active material coils around
the central core, we assume that the activation takes place in the tangential direction to the coil. A mathematically pleasing model for these structures is given by ring solutions with well-defined sectors of activation, each specified by a single angle, hence restricting the number of parameters. In this case, further analytical progress leads to an explicit form of the curvatures in terms of the Fourier decomposition of the activation functions. The sets of possible shapes of these structures, even in the simple case of a single active ring with a finite number of activation sectors, are remarkably rich. In particular, we showed that a chiral helically-wrapped filament can be tuned to create an achiral intrinsic shape with curvature but no torsion, or a structure with twist but without curvature. It is straightforward to consider these interesting limiting cases, since most of the derived expressions have an analytic form.

From an engineering perspective, the case of curvature without torsion corresponds to the typical application in metallic bilayer actuators. The possibility that one can also achieve twisting without curvature is more surprising, and it constitutes a type of actuation that could be of potential interest to the soft-robotics community.

Our analysis is limited to filaments that are initially straight. If the initial curvature is relatively small with respect to the length, we expect that the intrinsic curvature will be the sum of the initial curvature and the curvature induced by activation. However, for larger curvature, the analysis should be done properly, e.g., starting with a ring or helical initial configuration.

We generalized the ring solutions to the case of tapered filaments, another ubiquitous feature of the natural world. We showed that for a given tapering function, intrinsic curvatures can still be obtained, albeit at the expense of increasingly more complicated analytical formulas. Tapering provides yet another opportunity for control, especially in its ability to create large curvature at the small end of the filament. One would naturally expect that the intrinsic curvature increases as the radius decreases and, once the internal balance of forces is computed, this is mostly what we observe. Yet, the change in radius $R$ has another important effect, as it changes the stiffness of the structure. The typical scaling for the bending stiffness, inherited from the second moment of area, is $R^4$. Hence, the tapering not only affects the curvature, but also allows to connect a stiff region (large radii), that needs to support the weight of the filament, to a soft region (small radii) dedicated to fine manipulations. This is exactly what is observed in the massive elephant trunk in the animal kingdom.

The framework presented here provides a general analytical formulation for the problem of active filaments. It can now be adapted for specific challenges in physics and engineering — particularly, solving inverse problems found in robotics, where a given geometrical property or a final shape of a soft-robotic filament is sought, and the activation functions need to be determined. It can also be used to understand typical and universal design of natural manipulators, such as the elephant trunk.
